GRAINSIZE SCALES FOR MACROSCOPIC

AND MICROSCOPIC ROCK STUDIES

by

S. Ozimic

The information contained in this report has been obtained by the Department of Minerals and Energy as part of the policy of the Australian Government to assist in the exploration and development of mineral resources. It may not be published in any form or used in a company prospectus or statement without the permission in writing of the Director, Bureau of Mineral Resources, Geology and Geophysics.

INTRODUCTION

Grainsize is one of the most important characteristics of sedimentary rocks.

Descriptive grainsize terms, e.g. very coarse, coarse, medium, fine, very fine, are adequate for visual examination of sediments, but when it comes to a quantitative study the descriptive terms must be defined in a precise fashion and expressed in units of measurement.

The accompanying Tables 1 and 1a are the result of the author's experience in precise grainsize determination during petrologic and petrographic studies of sediments. The grainsize scales presented in the two tables apply equally well to the mechanical analysis of sediments and to studies by means of stereoscopic and polarizing microscopes. The section on microscopic grainsize scales can also be used in petrologic studies of non-sediments.

GRAINSIZE CLASSIFICATION OF SEDIMENTS

The measurement of grainsize is a precise operation, and the basic requirement is the choice of an appropriate scale. The grainsize scale devised by Udden (1914) is based on the constant ratio of 2 between successive classes. Wentworth (1922) gave specific names to various grainsize classes or intervals, and Krumbein (1938) devised the " ϕ " scale which is a logarithmic transformation of the Wentworth scale; because of simplified mathematical computations the " ϕ " scale has found preference for grainsize expression.

The predominant size of particles of which the rock is composed is the basis for subdivision into three types - GRAVEL, SAND, and MUD. The following grade names which have historical precedence and general authoritative acceptance (Twenhofel & Tyler, 1941; Pettijohn, 1957; and Folk, 1968) are proposed for each rock type:

Cobble is defined as 'a detached rock masses, somewhat rounded or otherwise modified by abrasion in transport with a size between size 64 and 256 mm'.

Pebble is a 'rock fragment larger than a coarse sand grain or granule and smaller than a cobble, which has been rounded or otherwise abraded by the action of water, wind, or glacial ice'. (Pettijohn, 1957) It is between 4 and 64 mm in diameter.

Gravel is an unconsolidated accumulation of pebbles, cobbles, or boulders and may be designated as pebble-gravel, cobble-gravel, etc. The consolidated equivalent is conglomerate, likewise designated pebble-conglomerate, etc.

Sand is the term used to denote an aggregate of mineral or rock grains greater than $1/16$ mm and less than 2 mm in diameter. The term arenite may be used instead of sand (as in Pettijohn, 1957, p.16). It is a descriptive term for clastic material of sand size without genetic or mineralogical connotations (Crook, 1960).

Mud comprises silt and/or clay, silt being an aggregate of fine-grained rock material greater than $1/128$ mm and less than $1/16$ mm in diameter; the clay fraction, being less than $1/16$ mm, is usually analysed by hydrometer or pipette method.

These terms may require finer distinction, e.g. very coarse sand, coarse sand, medium sand, fine sand. Consolidated equivalents are conglomerate, claystone, sandstone, siltstone.

NOTES ON THE USE OF TABLES 1 AND 1a

- Stereoscopic Microscope "NIKON SMZ" 10X Eyepieces - ZOOM

Example 1. A grain measures 16 graticule spaces under 0.8X objective.

∴ 16 graticule spaces = 2 mm; - 1ϕ.

Example 2. A grain measures 2.5 graticule spaces under 2.0X objective.

∴ 2.5 graticule spaces = $\frac{1}{8}$ mm; 0.125 mm; 125 micrometers; + 3ϕ.

- Polarizing Microscope "Leitz Laborlux" Binocular Head, 10X Eyepieces

Example 1. A grain measures 25 graticule spaces under 10.0X objective.

∴ 25 graticule spaces = $\frac{1}{4}$ mm; 0.25 mm; 250 micrometres; + 2ϕ.

Example 2. A grain measures 30 graticule spaces under 100.0X objective.

∴ 30 graticule spaces = $\frac{1}{32}$ mm; 0.031; 31 micrometres; + 5ϕ.

NOTE: Same method as above applies to Table 1a where the polarizing microscope has the 8.0X eyepieces.
